Sparisty-based Autofocus for Under-sampled Synthetic Aperture Radar

Shaun I. Kelly, Student Member, IEEE, Mehrdad Yaghoobi, Member, IEEE, and Mike E. Davies, Senior Member, IEEE.

Abstract—Motivated by the field of compressed sensing and sparse recovery, nonlinear algorithms have been proposed for the reconstruction of synthetic aperture radar images when the phase history is under-sampled. These algorithms assume exact knowledge of the system acquisition model. In this paper we investigate the effects of acquisition model phase errors when the phase history is under-sampled. We show that the standard methods of autofocus, which are used as a post-processing step on the reconstructed image, are typically not suitable. Instead of applying autofocus as a post-processor, we propose an algorithm that corrects phase errors during the image reconstruction. The performance of the algorithm is investigated quantitatively and qualitatively through numerical simulations on two practical scenarios where the phase histories contains phase errors and are under-sampled.

Index Terms—Synthetic Aperture Radar, autofocus, Compressed Sensing, Sparse Recovery, Blind Calibration, Block Relaxation Methods, Phase Retrieval

I. INTRODUCTION

SYNTHETIC aperture radar (SAR) is an active ground imaging system which is based on the coherent processing of multiple radar echoes. Typically, the reconstructed image is formed from the stored echos (phase history) using a linear approximation of the pseudo-inverse, e.g. polar format algorithm (PFA), range migration algorithm (RMA) or filtered back-projection. The approximate pseudo-inverse is an inverse which is defined on a finite region of the spatial frequency support of the reconstructed complex image. The size of this support is defined by the transmitted RF signal bandwidth and the size of the synthetic aperture. Ideally the reconstructed image would have a rectangular support in the spatial frequency plane so that the point spread function (PSF) would be a two-dimensional sinc function. This is approximately the case in systems where the synthetic aperture is uniformly sampled and the transmitted RF signal has a contiguous bandwidth. However, in a number of interesting non-standard SAR scenarios, this will not be true.

Two such systems that we will consider in this paper are multifunction and ultra wide band (UWB) SAR. In a multifunction SAR system, the radar antenna is used for multiple tasks which causes interruptions in the uniform acquisition of SAR data along the synthetic aperture [1], [2]. In the case of UWB SAR, the transmitted signal spectrum is broad and may contain frequency sub-bands that are in use by other communications systems or where transmission is not allowed.

To avoid interference, notch filters are commonly used in the transmitter and/or the receiver to avoid using these sub-bands [3], [4].

In both of these scenarios defining an inverse on an approximately rectangular spatial frequency support is ill-posed. Fig. 1 demonstrates why a rectangular support is sought by comparing the PSF of a rectangular spatial Fourier support and a randomly under-sampled aperture. In the PSF of the under-sampled aperture, unlike the ideal PSF, a significant amount of the target energy is contained in the side-lobes. Clearly this is undesirable. In order to make this problem well-posed, an appealing idea is to apply the tools and theory of compressed sensing (CS) and sparse recovery, for example [5] and [6].

The theoretical results of CS are based on exact knowledge of the linear acquisition system, however, in practical situations, such a system cannot be perfectly known. This is the case in SAR where the received phase history may contain significant phase errors due to imperfect system modelling. Methods for correcting these errors in fully-sampled systems are known as autofocus algorithms and are most commonly used as a post-processing method on the reconstructed image.

All autofocus algorithms require a signal model for either the phase errors and the image or both. Additionally, many algorithms make a far-field and small aperture angle approximation so that the phase errors are constant along the range axis of the reconstructed image. One of the earliest autofocus algorithms to be developed was the mapdrift (MD) algorithm [7]. MD estimates the phase errors based on a low-order polynomial model for the phase errors along the cross-range direction. Phase gradient autofocus (PGA), one of the most commonly used algorithms, requires the phase errors along the cross-range direction to vary smoothly and also requires the image to contain isolated point scatterers [8]. Recently another algorithm, multichannel autofocus (MCA), has been proposed which requires the focused image to contain a known region which is almost zero [9]. Although these post-processing autofocus methods have been very successful for correcting phase errors in fully-sampled scenarios, they may not be suitable for under-sampled SAR.

The algorithm proposed in this paper for image reconstruction and autofocus of a under-sampled phase history has similarities with the proposed method in [10]. Although the method proposed in [10] primarily concentrates on the fully-sampled scenario it does demonstrate that it is also applicable to the under-sampled scenario. Both methods involve approximately solving the same non-convex problem but our algorithm has some additional practical benefits. Firstly, it can be shown to
be stable and it produces a sequence that convergences to a set of connected set. Secondly, it empirically converges in a significantly smaller number of iterations.

A closely related problem which has been investigated in the signal processing literature in the last few years is the problem of phase retrieval, e.g. [11] and [12]. The goal of phase retrieval is to recover a complex signal from magnitude only measurements. The SAR imaging and autofocus problem is equivalent to the phase retrieval problem if we ignore all phase information due to a belief that it is corrupted. In these papers a technique known as “phase-lifting” is used to pose a convex problem which is solved to recover the signal. This technique involves “lifting” the signal so instead of recovering \( x \in \mathbb{C}^N \) the algorithm recovers \( X = x x^H \in \mathbb{C}^{N \times N} \). This process is likely to be very costly computationally and will likely make these techniques infeasible for SAR systems.

**Contributions of the paper**

The main contributions of this paper are as follows. We show using CS theory and numerical simulations that standard post-processing autofocus methods are unsuitable for under-sampled SAR. We analyse under what conditions the image reconstruction and autofocus problem is well-posed. Also, we propose a new algorithm that correct phase errors within the image reconstruction algorithm. Empirically, we show that this algorithm converges faster than existing methods and then theoretically we show that it is stable and convergent, which cannot be said of the existing algorithms. We also verify the performance using two practical scenarios.

**Organisation of the paper**

In Section II a brief background on relevant CS results is provided. Then in section III a SAR acquisition model is developed which includes phase errors. In Section IV the expected performance of existing post-processing autofocus methods in a CS framework are investigated. Inherent ambiguities in the under-sampled phase error problem are analysed in Section V. A reconstruction algorithm for under-sampled SAR with phase errors is proposed in Section VI. Finally experimental simulations in Section VII are used to demonstrate the effectiveness of the proposed algorithm.

**Notation**

The following is a description of the notational conventions used within this paper.

Matrices and vectors will be denoted by upper and lower case boldface symbols respectively (e.g. \( X \) and \( x \)). Elements of matrices and vectors will be lower case lightface and will be indexed by subscripts, e.g. the element in the \( m \)th row and the \( n \)th column of a matrix \( X \) is denoted by \( x_{mn} \).

The complex conjugate of a complex scalar \( x \) will be \( x^* \) and the complex conjugate transpose of a vector or matrix will have a superscript \( H \), e.g. \( X^H \). \( X^\dagger \) is used to indicate the pseudo inverse of \( X \).

We define diag\{\( x \)\} to be a square matrix with the elements of the vector \( x \) along its main diagonal. \( \text{Re}\{ x \} \) will denote the real part of a complex scalar \( x \).

The following notation is for matrix and vector norms. \( \| \cdot \|_0 \) denotes the “counting norm” which is equal to the number of non-zero elements in a vector or a matrix. \( \| \cdot \|_F \) and \( \| \cdot \|_1 \) are element-wise two and one matrix norms respectively. Finally, \( \| h \|_2 = \sup \{ \| h(X) \|_F \} \) with \( \| X \|_F = 1 \) is the operator norm of a linear operator \( h \).

**II. COMPRESSED SENSING: BACKGROUND**

CS theory provides a theoretical framework which can be used to analyse the reconstruction performance of an under-determined linear system, e.g.

\[
y = Ax + n,
\]

where, \( y \in \mathbb{C}^M \) are the measurements, \( A \in \mathbb{C}^{M \times N} \) is the system model, \( x \in \mathbb{C}^N \) is the original signal and \( n \in \mathbb{C}^M \) is complex Gaussian noise for \( M < N \). Without any further information, the best approximation, in the MMSE sense, of \( x \) is given by the pseudo inverse \( A^\dagger y \). However, using the tools of CS we may be able to produce a better estimate if \( x \) is sparse or well approximated by a sparse signal in an orthogonal basis, i.e.

\[
x = \Psi \alpha,
\]

where, \( \Psi \in \mathbb{C}^{N \times N} \) is an orthogonal basis and \( \alpha \in \mathbb{C}^N \) is either a sparse vector, i.e. \( \| \alpha \|_0 \leq K \) for \( K \ll N \), or is close to its best \( K \)-term approximation \( \alpha_K \), i.e. \( \| \alpha - \alpha_K \|_2 \approx 0 \). As well as the sparsity conditions on \( x \) we also require certain conditions on the matrix \( A\Psi \) to hold. A property
that is commonly used to define sufficient conditions on \( A\Psi \) is the so-called restricted isometry property (RIP) [13]. A matrix \( A \) satisfies the (symmetric) RIP of order \( K \) if for all vectors \( x \) with no more than \( K \) non-zero entries there exists a (symmetric) RIP constant \( \delta_K < 1 \) which satisfies the following inequalities:

\[
(1 - \delta_K) \|x\|_2^2 \leq \|Ax\|_2^2 \leq (1 + \delta_K) \|x\|_2^2. \tag{1}
\]

If \( x \) satisfies the sparsity conditions and \( A\Psi \) satisfies a \( 2K \) order (symmetric) RIP with RIP constants that satisfy the following inequality:

\[
\delta_{2K} < \frac{3}{4 + \sqrt{6}} \approx 0.46515, \tag{2}
\]

then \( x \) can be stably reconstructed from \( y \) using the following convex optimisation program [14]:

\[
\begin{align*}
\text{minimise} & \quad \|\alpha\|_1 \\
\text{subject to} & \quad \|y - A\Psi\alpha\|_2 \leq \sigma.
\end{align*} \tag{3}
\]

The solution of Eq. (3), \( \hat{x} = \Psi\hat{\alpha} \), will be stable in the following sense

\[
\|\hat{x} - x\|_2 \leq C_{1,K} \sigma + C_{2,K} \frac{\|x - x_K\|_1}{\sqrt{K}}, \tag{4}
\]

where, \( \sigma = \|n\|_2 \) and \( C_{1,K} \) and \( C_{2,K} \) are constants [15]. In words, our solution will be bounded by something that is proportional to the noise energy \( \sigma \) and the error associated with the best \( K \)-term approximation of \( x \).

Although there is no computationally efficient way to check Eq. (2) for arbitrary matrices there are interesting asymptotic results for random matrices. One such result [16] is if \( A \) is formed from \( M < N \) random columns of a Fourier matrix and \( \Psi \) is an identity matrix then with overwhelming probability the matrix \( A \) satisfies Eq. (2) if \( M \) is of the order

\[
M = \mathcal{O}(K \log^4(N)) \tag{5}
\]

This result motivates the use of CS theory for under-sampled SAR. If the under-sampled SAR observation matrix is similar to a randomly under-sampled Fourier matrix and our image contains only a small number of bright targets in clutter we may be able to make a good approximation of the image by solving a convex optimisation program.

### III. SAR Generative Model with Phase Errors

Since SAR systems are a coherent imaging system, the round trip propagation delay to a reference position in the scene must be estimated at each position along the aperture. In spotlight mode SAR this reference point is the scene centre. Errors in this estimate, which can be due to a non-idealised propagation medium or inaccuracies in the inertial navigation system, introduce unknown phase errors into the acquired data. If not corrected, phase errors can degrade and produce distortions in the reconstructed image.

If we consider a simplified spotlight-mode SAR system after dechirp-on-receive, adding a delay error \( \tau_e \) at each aperture position produces the following discretized system model [17],

\[
y_{kl} = e^{j\phi_{kl}} \sum_{m=1}^{M} \sum_{n=1}^{N} x_{mn} \exp \left\{ -j \frac{2\pi m n k}{c} \right\}; \tag{6}
\]

where, \( y = \{y_{kl}\} \in \mathbb{C}^{M' \times N'} \) is the phase history, \( X = \{x_{mn}\} \in \mathbb{C}^{M \times N} \) are the scene reflectivities, \( \{\phi_{kl}\} = (\omega_0 \tau_{ek} - \alpha \tau^2_{ek}) + 2\alpha \tau_{ek} (T_s - \tau_0) \in \mathbb{C}^{M' \times N'} \) are the phase errors which result from the delay errors, \( \{u_{mnk}\} \in \mathbb{R}^{M \times N \times M'} \) are the distances between each element in the scene and each aperture position, \( c \) is the speed of light, \( \tau_0 \) is the true propagation delay to the scene centre, \( T_s \) is the range sampling period, \( 2\alpha \) is the chirp rate and \( \omega_0 \) is the carrier frequency. If we neglect the effects of the linear phase term, which is a valid approximation in most systems where \( \tau_e \ll T_s \), the discrete SAR observation model with phase errors becomes:

\[
Y = \text{diag} \{e^{j\phi}\} h(X), \tag{7}
\]

where, \( h : \mathbb{C}^{M \times N} \rightarrow \mathbb{C}^{M' \times N'} \) is a linear map that models the ideal SAR observation model (the summation in Eq. (6)) and

\[
\phi_{k} = \omega_0 \tau_{ek} - \alpha \tau^2_{ek} \tag{8}
\]

are the phase errors.

Clearly, without further assumptions, the problem of recovering \( \phi \) and \( X \) from \( Y \) is ill-posed if \( M' = M \) and \( N' = N \), since there are only \( MN \) equations and \( MN + 1 \) unknowns.

### IV. CS with Post-Processing Autofocus

Most post-processing autofocus methods make a far-field and small aperture angle approximation in the SAR acquisition model [17], i.e. the image was formed using a separable two-dimensional imaging method such as range-Doppler imaging [18]. Under the separable approximation and assuming we sample at exactly the Nyquist rate in range and cross range, the system can be modelled as the following LHS and RHS matrix multiplication:

\[
Y = \text{diag} \{e^{j\phi}\} AXB, \tag{9}
\]

where,

\[
a_{mn} = \exp\left\{ -j(2\pi(m-1)(n-1)/M - (m-1)\pi - (n-1)\pi + M\pi/2) \right\}
\]

and

\[
b_{mn} = \exp\left\{ -j(2\pi(m-1)(n-1)/N - (m-1)(2\pi\omega_0/2\alpha T - \pi) - (n-1)\pi + N\pi/2 - 2\omega_0 L/c) \right\}
\]

are the elements of the cross-range matrix \( A \in \mathbb{C}^{M \times M} \) and the range matrix \( B \in \mathbb{C}^{N \times N} \), respectively, where, \( L \) is the scene radius and \( T \) is the chirp period.

Since, \( A \) is essentially a Fourier matrix, we can rewrite the observation model in Eq. (9) as

\[
Y = A\Psi X B, \tag{10}
\]

where, \( \Psi \) is a circulant matrix which may be viewed as a filter in cross-range direction for each range bin.
When fully-sampled, recovering $\Psi X$ from $Y$ is straightforward because $A$ and $B$ are invertible. Post-processing autofocus algorithms recover $X$ from the filtered image $\Psi X$, by using a signal model for $\Psi$ and/or $X$.

When $Y$ is under-sampled in either range or cross-range the observation model will be:

$$Y' = A\Psi XB'$$  \hspace{1cm} (10)

or

$$Y' = A'\Psi XB'.$$  \hspace{1cm} (11)

where, $A' \in \mathbb{C}^{M' \times M}$ is a $M' < M$ row subset of $A$ and $B' \in \mathbb{C}^{N' \times N'}$ is a $N' < N$ column subset of $B$. With this model, unlike in the fully-sampled situation, $A'$ and $B'$ are not invertible. However, CS results can be used to analyse the expected reconstruction quality of $\Psi X$ when it is reconstructed by solving Eq. (3).

If the under-sampling is random, a sufficient order for the number of cross-range samples required for stable reconstruction is $O(K \log^4(M))$, for, $K = K_{\psi m} K_X$, where, $K_{\psi m}$ and $K_X$ are the maximum required number of non-zero elements needed to accurately approximate the rows of $\Psi$ and the columns of the true image $X$, respectively. The reconstruction is stable in the sense that the columns of the recover image $\tilde{\Psi}X$ satisfy Eq. (4).

It is clear that the number of samples required for a stable reconstruction scales with $K_{\psi m}$ and thus the introduction of phase errors increases the number of samples required for stable reconstruction. For this reason, in most cases, post-processing autofocus methods are unsuitable for under-sampled SAR.

V. Uniqueness

It is well known that there are inherent ambiguities in the autofocus problem which prevent the problem having a unique solution. The formulation in Eq. (9) is known to be ambiguous to constant and linear phase errors [17].

A sparsity based necessary condition for the uniqueness of the autofocus problem can be given which is dependent on the observation model $h$ and the signal model of the scene $X$. It is given as follows:

$$h(\tilde{X}) = \text{diag}(d)h(X) \iff \tilde{X} = \beta X,$$  \hspace{1cm} (12)

and

$$\forall \beta \in \{ \beta \in \mathbb{C} : |\beta| = 1 \},$$

$$\forall (\tilde{X}, X, d) \in \{ \tilde{X} \in \mathcal{X}, X \in \mathcal{X}, d \in \mathcal{D} \},$$

where,

$$\mathcal{X} = \{ X \in \mathbb{C}^{M \times N} : \|X\|_0 \leq K \},$$

i.e. we know the scene has at most $K$ scatters, and

$$\mathcal{D} = \{ d \in \mathbb{C}^{M'} : |d_m| = 1 \}$$

is the set of all possible phase errors.

If Eq. (12) is satisfied then the problem is unique up to a scalar $\beta$ multiplication of the true $X$, i.e. $\tilde{X} = \beta X$, and the solutions are given by the following program:

$$\begin{align*}
\text{minimise} & \quad \|X\|_0 \\
\text{subject to} & \quad \text{diag}(d)Y = h(X)
\end{align*}$$

$$d_m^* d_m = 1, \; m = 1, \ldots, M,$$

where, $\| \cdot \|_0$ measures the number of non-zeros matrix elements.

Eq. (12) states that the phase error free observation model $h$ must have the property that the phase history of a sparse image cannot be equal to a phase error corrupted phase history of a difference sparse image.

In Appendix A, we give additional conditions for the uniqueness of the separable model where we have sub-sampling only in the cross-range direction.

VI. Sparse Reconstruction and Autofocus

In this section our goal is to design algorithms which perform sparse reconstruction and autofocus and are able to be solved or approximately solved in a polynomial time. To this end, the non-convex function $\|X\|_1$ in Eq. (13) is replaced with its closest convex function $\|X\|_1$ and the equality constraint is replaced with an inequality constraint that accommodates noise. This results in:

$$\begin{align*}
\text{minimise} & \quad \|X\|_1 \\
\text{subject to} & \quad \|\text{diag}(d)Y - h(X)\|_F \leq \sigma
\end{align*}$$

$$d_m^* d_m = 1, \; m = 1, \ldots, M.$$  \hspace{1cm} (14)

Even though our objective function is now convex, Eq. (14) is still non-convex because the inequality constraint is not linear and therefore does not define a convex feasible set.

In order to use gradient based methods, which are usually used in large scale problems such as SAR reconstruction, the objective must be smooth. Therefore it is convenient to exchange to the inequality constraint and the objective in Eq. (14) to form the equivalent program:

$$\begin{align*}
\text{minimise} & \quad \|\text{diag}(d)Y - h(X)\|_F^2 \\
\text{subject to} & \quad \|X\|_1 \leq \tau
\end{align*}$$

$$d_m^* d_m = 1, \; m = 1, \ldots, M.$$  \hspace{1cm} (15)

Note, there is a one-to-one map, $\gamma : \sigma \rightarrow \tau$ if $0 \leq \sigma \leq \|Y\|_F$. Even though the problem is still non-convex, importantly, in each set of variables $X$ and $d$—with the other fixed—we have a unique solution. This observation allows us to use a block relaxation type method which can be used to approximate the solution and has been found to be effective in the related problem of dictionary learning [19].

Block relaxation methods approximately solve Eq. (15) by iteratively solving the problem based on a single parameter block, $X$ or $d$, at a time.
A. Minimisation based on $X$

Consider Eq. (15) when $d$ is fixed, i.e.

$$\begin{align*}
\text{minimise} & \quad f(X, d) \\
\text{subject to} & \quad \|X\|_1 \leq \tau,
\end{align*}$$

(16)

where,

$$f(X, d) = \|\text{diag} \{d\} Y - h(X)\|_F^2,$$

(17)

A method used for solving Eq. (16) is a technique known as "majorisation minimisation". This technique replaces the objective function with a majorising surrogate function which is much easier to solve. A function $g$ is said to majorise $f$ if $f(\omega) \leq g(\omega, \xi)$ and $f(\omega) = g(\omega, \omega), \forall \omega$ and $\xi \in \mathcal{Y}$, where, $\mathcal{Y}$ is the parameter space. A surrogate function can be derived for (17) by expanding it as a Taylor series and bounding its curvature ($d^2 f$) [19]. This surrogate function is:

$$g(X, X^\dagger, d) = \|\text{diag} \{d\} Y - h(X)\|_F^2 - \|h(X) - h(X^\dagger)\|_F^2 + L_X \|X - X^\dagger\|_F^2,$$

where, $L_X > \|h\|_F^2$. Replacing the objective function with its surrogate function, Eq. (16) becomes

$$\begin{align*}
\text{minimise} & \quad g(X, X^\dagger, d) \\
\text{subject to} & \quad \|X\|_1 \leq \tau,
\end{align*}$$

(18)

which is a minimisation based on $X$ and a surrogate parameter vector $X^\dagger$. In this program, if $X$ is fixed, the minimum of Eq. (19) occurs at $X^\dagger = X$ and if $X^\dagger$ is fixed the minimum occurs at

$$\begin{align*}
\text{minimise} & \quad \|X - C\|_F \\
\text{subject to} & \quad \|X\|_1 \leq \tau,
\end{align*}$$

(19)

where, $C = X^\dagger + \frac{1}{L_X} h^H(\text{diag} \{d\} Y - h(X^\dagger))$. The solution of Eq. (20) is the projection of $C$ onto an $\ell_1$ ball with a radius of $\tau$. There are efficient methods to exactly compute this projection [20].

By minimising Eq. (19) based on either $X^\dagger$ and $X$ in an alternating fashion, $X^\dagger$ and $X$ will converge to the solution of Eq. (16) [21]. In practice a feasible $L_X$ can determined using a backtracking line-search.

B. Minimisation based on $d$

Consider Eq. (15) when $X$ is fixed, which (ignoring constant terms) is given by:

$$\begin{align*}
\text{minimise} & \quad \text{tr} \left\{ -2 \text{Re} \left\{ \text{diag} \{d^H\} h(X) Y^H \right\} \right\} \\
\text{subject to} & \quad d_m^* d_m = 1, \ m = 1, \ldots, M.
\end{align*}$$

(21)

The unique solution of Eq. (21) can be found analytically by.

$$d = e^{i \angle \text{diag} \{h(X) Y^H\}}.$$
VII. EXPERIMENTAL RESULTS

In these experiments we investigate the performance of Algorithm 1 and Algorithm 2 using under-sampled phase histories that contain phase errors.

A. Quantitative Performance

In the first experiment we investigate the empirical convergence rate and reconstruction performance of Algorithm 1 and Algorithm 2. In order to easily compare with post-processing autofocus techniques, we consider the separable model, Eq. (9). In this experiment the scene consists of a small number of constant amplitude point targets randomly placed in the scene. The under-sampling consists of selecting a random subset of the fully-sampled synthetic aperture. Two different phase errors were consider: quadratic phase errors \( \phi_m = \gamma((m-1)/M)^2 \) which model platform velocity measurement errors and normally distributed phase errors \( \phi_m = N(0, \gamma^2) \). The parameters for the synthetic model are in Table I.

| TABLE I SAR SYSTEM PARAMETERS FOR SYNTHETIC EXPERIMENTS |
|---------------------------------|---|
| parameter                      | value                |
| carrier frequency \( (\omega_c) \) | \( 2 \pi \times 10^9 \) rad/s |
| chirp bandwidth \( (2\alpha T) \)   | \( 2 \pi \times 150 \times 10^9 \) rad/s |
| scene radius \( (L) \)             | 50 m                  |
| number of targets               | 20                    |
| signal to noise ratio           | 0 dB                  |

1) Convergence: In this experiment we compare the number of iterations it takes Algorithm 1 and Algorithm 2 to reach the stopping criterion when the threshold is \( 10^{-6} \). In order to fairly compare the two algorithms we compute the operation \( D \) in Algorithm 1 using the “majorisation minimisation” method from Section VI-A. We also define the number of iterations in each algorithm to be the total number of times the gradient of the objective function has to be computed with respect to \( X \). We select this definition because the main computational cost of both algorithms is consumed by computing this gradient, therefore, the iterations count will closely rate to the algorithm’s execution time. We choose to show the results for normally distributed phase errors with \( \gamma = 10 \). This is because the type and magnitude of phase errors was found to have only a minor effect on the results.

As expected Fig. 2(a) shows that Algorithm 2 requires many less iterations than Algorithm 1. This will likely be due to the minimisation path of Algorithm 1 oscillating around the optimal minimisation path.

A technique known as continuation has been found to be useful for increasing the numerical convergence rate of \( \ell_1 \) sparse recovery algorithms when there is no phase errors [24]. Continuation involves varying the value of \( \tau \) during the iterations of the algorithm. The motivation for this technique is based on the observation that the convergence rate depends on \( \tau \). The smaller than value of \( \tau \), the faster the algorithm will converge. Therefore, a method of continuation is to start with a small value of \( \tau \) and increases its value in the following iterations until it reaches the desired final value.

In order to further improved the convergence rate of our algorithm we experimented with a continuation scheme. Although we did not see any singularity in the modified algorithm with this setting, the convergence and stability would need to be proved in the future.

In this simulation we used a continuation scheme that involved changing \( \tau \) during the first \( I \) iterations by the rule \( \tau_i = i \tau / I \) for \( i = 1, \ldots, I \). The selection of a “good” \( I \) depends on the under-sampling so we used the following values of \( I \) for each under-sampling percentage.

| TABLE II CONTINUATION PARAMETERS |
|---------------------------------|---|
| sampling ratio (%)              | 20 | 26 | 32 | 38 | 44 | 50 | 56 | 62 | 68 | 74 |
| \( I \)                         | 30 | 20 | 10 | 5  | 3  | 2  | 1  | 1  | 1  | 1  |

Fig. 2(b) shows a small improvement in performance when continuation is used. Another method for reducing the required number of iterations would be to use a more aggressive step size, similar to what is used is other \( \ell_1 \) sparse recovery algorithms. Using this type of step size, the stability of the algorithm cannot be guaranteed but in practise it may also be useful.

2) Reconstruction Error: In order to assess the image reconstruction performance of the autofocus methods we define an image quality metric. Since the autofocus problem is ambiguous to scalar multiplication by \( \beta \in \{ \beta \in \mathbb{C} : |\beta| = 1 \} \) and cyclic permutation, we define a metric that is immune to these ambiguities. We will refer to this metric as relative SNR and define it as:

\[
\text{minimise } \beta, n \left\{ 10 \log_{10} \left( \frac{\|\hat{X}\|_F^2}{\|\hat{X} - \beta P^n X\|_F^2} \right) \right\},
\]

where, \( n \in \mathbb{Z} \) and
Fig. 3. Phase error induced filters: the rows of $\Psi$ for quadratic and random phase errors with different $\gamma$. Quadratic: (a) $\gamma = 0.1$ (c) $\gamma = 1$ (e) $\gamma = 10$. Random: (b) $\gamma = 0.1$ (d) $\gamma = 1$ (f) $\gamma = 10$.

Fig. 4 shows the reconstruction performance of oracle post-processing autofocus and Algorithm 2 with different phase errors. We do not show the results of Algorithm 1 because the results are virtual identical. We refer to the oracle post-processing autofocus because we use a $\ell_1$-norm spectral projected gradient (SPG) method [21] to recover the filtered image and then correct it to recover the image using oracle knowledge of the phase errors. To provide an empirical upper-bound, we also show the reconstruction performance that can be achieved with oracle knowledge of the phase errors and also the locations of the targets, we refer to this as the oracle reconstruction. The magnitude of the corresponding filters for each of the phase errors, the rows of $\Psi$, are shown in Fig. 3. As predicted in Section IV, as the value of $K_{\psi,\alpha} \gamma$ increases, corresponding to an increase in $\gamma$, the performance of post-processing autofocus techniques decreases, while the performance of Algorithm 2 is consistent.

B. Qualitative Performance

In these experiments we wish to show that the presented algorithm works on realistic simulations of our two motivating scenarios, i.e. multifunction and UWB SAR. The scene used in both simulated scenarios consists of four point targets which reflect back an equal amount of energy. Fig. 5 is a block diagram which illustrates the basic elements used to create the simulated phase histories. Firstly, the analog signal that would be received at each aperture position is simulated by summing scaled and delayed versions of the transmitted chirp where the scaling and delay correspond to the reflectivity and the signal travel time for each point target. For each position an additional delay is added to the analog received signal to model system inaccuracies. Each analog signal is then dechirped and IF filtered which simulates the analog receiver in a dechirp-on-receive system. Finally, the analog to digital sampling is simulated by down sampling the signals to a sample rate proportional to the IF bandwidth and the Residual Video Phase (RVP) term is removed.

1) UWB SAR: As mentioned previously, under sampling occurs in a UWB SAR system when notches are introduced into the transmitted chirp in order to avoid interference with other users. In this simulation we used a notched linear frequency chirp which had a spectral density that is given in Fig. 6. The chirp contains five notches which equate to a nulling of approximately 20% of the chirp spectrum.

The other parameters of the simulation are given below.
2) **Multifunction SAR**: In this simulation a randomly undersampled aperture of a X-band SAR system is used simulate a multifunction SAR system. The phase history contains a 50% random subset of the fully-sampled aperture. The other parameters of the simulation are given below.

For both scenarios, three SAR images where formed using different reconstruction methods. One image in each scenario was generated using filtered back-projection without any form of autofocus. Another was generated using 20 iterations of a $\ell_1$-norm SPG method again without any form of autofocus. The last image was created using 20 iterations of the modified Algorithm 2 which uses continuation with $I = 15$. The final value of $\tau$ was selected to be the sum of the absolute values of the target reflectivities. However, the reconstruction performance was found to be not particularly dependent on this parameter. In a real system a suitable $\tau$ could be selected with only a coarse degree of parameter tuning. In the iterative reconstruction algorithms both the observation model and its

---

- For both scenarios, three SAR images where formed using different reconstruction methods. One image in each scenario was generated using filtered back-projection without any form of autofocus. Another was generated using 20 iterations of a $\ell_1$-norm SPG method again without any form of autofocus. The last image was created using 20 iterations of the modified Algorithm 2 which uses continuation with $I = 15$. The final value of $\tau$ was selected to be the sum of the absolute values of the target reflectivities. However, the reconstruction performance was found to be not particularly dependent on this parameter. In a real system a suitable $\tau$ could be selected with only a coarse degree of parameter tuning. In the iterative reconstruction algorithms both the observation model and its
adjoint \( (h(.)) \) are computed using the fast (re/back)-projection algorithms from \[23\].

The resulting images from both simulation scenarios are contained in Fig. 7 and Fig. 8. It should be noted that these images have had been padded with zeroes in the spatial Fourier domain to make the images twice the size of the reconstructed images. This is done to more clearly display the point targets which are sometimes unable to be clearly viewed when they consist of only a single or a small number of non-zero pixels.

Fig. 7(a) and Fig. 8(a) demonstrate the adverse effects of phase errors and under-sampling. The side-lobes of the four targets contain a large amount of energy which deteriorates the SAR image quality. The images in Fig. 7(c) and Fig. 8(c) which were produced using an \( \ell_1 \) sparse recovery algorithm have an improved visual quality over the previous images due to the sparsity promoting algorithm. However, due to the model inaccuracies there are a large number of non-zeros pixels that may be mistaken for additional targets. Finally, Fig. 7(e) and Fig. 8(e) show the results of Algorithm 2. In these images the energy from each target is highly concentrated around the target locations. It is clear, therefore, in these scenarios Algorithm 2 can produce a visually improved SAR image, with a rectangular spatial Fourier support and a sparse number of point targets, from a phase history that is under-sampled and contains model inaccuracies.

VIII. CONCLUSION

We have investigated the effects of phase errors on a under-sampled SAR system. We have shown that post-processing autofocus algorithms are typically unsuitable when there is under-sampling and a sparse reconstruction method is employed. Instead, phase errors should be corrected during image reconstruction.

We have proposed a new algorithm that corrects phase errors within the image reconstruction algorithm. Algorithm 2, which is an algorithmically stable generalisation of a recently proposed non-convex sparsity based autofocus method, performs consistently well for a variety of phase errors and under-sampling ratios and was found empirically to converge in a much smaller number of iterations.

We have also demonstrated through additional realistic simulations that Algorithm 2 could be used in practical non-standard SAR image reconstruction systems to produce sparse SAR images from a under-sampled phase histories which contain model inaccuracies.

APPENDIX A

Using ideas from the dictionary learning literature \[25\] we can define a set of sufficient conditions for the uniqueness of \( \phi \) and \( X \) given \( Y' = \text{diag} \{ d' \} A'X B \). These conditions are as follows:

1) the spark condition: any \( 2K_X \) columns of \( A' \) are linearly independent
2) the columns of \( X \) have exactly \( K_X \) non-zero elements
3) for each of the \( \binom{K_X}{K_X} \) possible \( K_X \)-sparse supports, there are at least \( K_X + 1 \) columns of \( X \)
4) any \( K_X + 1 \) columns of \( X \) which share the same support, span a \( k \)-dimensional space
5) any \( K_X + 1 \) columns of \( X \), which have different supports, span a \( (K_X + 1) \)-dimensional space

Proposition 1 (see \[25, Theorem 3\]): If the above conditions hold then there is a unique \( X \) which satisfies \( \text{diag} \{ d' \} A'X B \). Where uniqueness is up to a unit magnitude scalar \( \beta \) and a circular permutation \( P^m \) of the true \( X \), i.e. \( \bar{X} = \beta P^m X \).

As is the case in dictionary learning, the richness condition 3 is completely unrealistic for compressively sampled SAR. However, this condition is only sufficient and is likely to be very pessimistic. It should also be noted that recovering the uniqueness solution involves solving Eq. (13) which requires combinatorial many operations to solve and is unsuitable for practical problems that involve noise.
